1 Background

The visual display of data represents an intuitive form of data presentation. Data visualizations work on multiple dimensions and possess the potential to convey intricate relationships that single statistics or tables never can.

Such visualizations, however, are only effective if their aesthetics convey relationships. Consider, for instance, a disc with a radius of 2 cm labelled *Men*—it says nothing by itself; yet if we juxtapose it with a 1 cm-radius disc labelled *Children*, the graphic starts to become informative: it now displays the relation between two quantities. Now, if we intersect the two discs, so as to produce an overlap, we have successfully visualized the relative proportions of men and men, as well as their intersection. The diagram we have constructed is a *Euler diagram* (Figure 1.1).

The Euler diagram, originally proposed by Leonard Euler [1], is a superset of the obiquiteous *Venn diagram*: a staple of introductory text books in statistics and research disciplines such as biomedicine and geology. Venn and Euler diagrams differ in that the the former require all intersections to be present—even if they are empty—whilst Euler diagrams do not.

Euler diagrams may moreover be area-proportional, which is to say that each separate surface of the diagram maps to some quantity. (This was the case with the diagram with defined in the second paragraph.) This is a rational form for a Euler diagram—only its geometries are necessary to interpret it, letting us, for instance, to discard numbers without crucial loss of information; the same cannot be said for a Venn diagram.

Area-proportional Euler diagrams may be fashioned out of any closed shape, and have been implemented for triangles [2], rectangles [2], ellipses [3], smooth curves [4], polygons [2], and circles [2, 5, 6]. Circles is the popular choice, and for good reason, since they are easiest to interpret [7]. In spite of this, circles do not always lend themselves to accurate representations. Consider, for instance the following three-set relationship:

$$\begin{aligned} A &= B = C = 2, \\ A \cap B &= A \cap C = B \cap C = 1 \\ A \cap B \cap C &= 0. \end{aligned}$$

There is no way to visualize this relationship perfectly with circles because they cannot be arranged so that the $A \cap B \cap C$ overlap remains empty whilst $A \cap B$, $A \cap C$, and $B \cap C$ are non-empty. With

Figure 1.1. The merits of Euler diagrams.

ellipses, however, we can solve this problem since they can both be stretched and rotated, enabling a perfect fit (Figure 1.2). In essence, circles feature three degrees of freedom: a center consisting of x - and y -coordinates h and k , as well as a radius r . Ellipses, meanwhile, have five: the aforementioned h and k , a semi-major axis a , a semi-minor axis b , and an angle of rotation ϕ .

With four or more intersecting sets, exact circular Euler diagrams are in fact impossible, given that we *require* 15 intersections but with four circles can yield at most 13 unique overlaps. This is not the case with ellipses, which may intersect in up to four, rather than two, points. The only implementation of elliptical Euler diagrams is found in **eulerAPE** [3], yet it only supports three sets that are moreover required to intersect. The diagram in Figure 1.3, for instance, would not be possible with **eulerAPE**.

Euler diagrams do not reduce to analytical solutions [8] and have to be solved numerically. Most implementations accomplish this in two steps, first finding a rough initial estimate that is then finalized in a second, more accurate, algorithm. For the initial configuration, **eulerAPE** [9], for instance, uses a greedy algorithm that tries to minimize the error in the three-way intersection. **venneuler** [5] uses multi-dimensional scaling with Jacobian distances, taking only pairwise relationships into account. **venn.js** [10] uses a constrained version of the latter that is instead based on euclidean distances and separately runs a greedy algorithm, picking the best fit out of the two. **Vennerable** [2] uses a simple method of computing the required pairwise distances between circles and then changes the largest to attempt to arrive at accurate two-way overlaps. All the algorithms use circles in the initial configuration.

Diagrams with more than two sets normally require additional tuning, which may be dealt with in a final configuration step. The prerequisite for this is that we first compute the areas of the overlaps in order to establish how well our diagram fits the input. Calculating overlaps, however, is no trivial task, particularly not for ellipses. This is evident in that most methods resort to approximations such as quad-tree binning [5], polygon intersecting [6], or restricting the algorithm to pairwise overlaps [2]. Frederickson [10], contrastingly, computes areas exactly, yet only for circles. These three approaches moreover allow only circles, whilst Micallef and Rodgers [3], on the other hand, compute areas exactly also for ellipses, though only for a maximum of three.

Compared to approximative methods, exact algorithms require that we first find all the intersection points between the ellipses, for which there are several approaches. Some rely on solving the system of equations formed by two ellipses to be intersected, which necessitates solving a fourth-degree polynomial; other methods make use of the representation of an ellipse as a conic in projective geometry, which involves solving a third-degree polynomial. These

Figure 1.2. A set relationship depicted erroneously with circles and perfectly with ellipses.

Figure 1.3. A Euler diagram with a subset relationship.

methods vary in execution time but are all accurate up to floating-point precision.

With all the intersection points at hand, the areas of the overlaps can be established. Frederickson [11] has published a method for circles and a similar method is used by Micallef and Rodgers [3] for three ellipses. No method has so far been published that generalizes these methods to diagrams of more than three ellipses or ellipses with subset or disjoint relationships.

1.1 Aims

Elliptical Euler diagrams have previously not been implemented for more than three sets or for three-set diagrams with subset or disjoint relationships. This is the motivation for this thesis, with which we aim to present a method and implementation for constructing and visualizing Euler diagrams for sets of any numbers using ellipses and exact area computations.

2 Method

Constructing a Euler diagram is analagous to fitting a statistical model in that you need

1. data,
2. a model to fit the data on,
3. a test to assess the model fit, and
4. a presentation of the result.

In the following sections, we explain how **eulerr** adressess each of these items in turn.

2.1 Input

The data for a Euler diagram is always a description of set relationships. **eulerr** allows several alternatives for this data, namely,

- intersections and relative complements¹,
- unions and identities²,
- a matrix of binary (or boolean) indices³,
- a list of sample spaces⁴, or
- a two- or three-way table ⁵.

As an additional feature for the matrix form, the user may supply a factor variable with which to split the data set before fitting a Euler diagram to each split. This is offered as a convenience function for the user since it may be that the solution is more well-behaved after such a split.

Whichever type of input is provided, **eulerr** translates it to the first, *intersections and relative complements* (Definition 2.1), which is the form used later in the loss functions of the initial and final optimizers.

$$^1 A \setminus B = 3 \quad B \setminus A = 2 \quad A \cap B = 1$$

$$^2 A = 4 \quad B = 3 \quad A \cap B = 1$$

$$^3 \begin{bmatrix} A & B & C \\ 0 & 1 & 0 \\ 1 & 1 & 1 \\ 1 & 0 & 0 \end{bmatrix}$$

$$A = \{ab, bb, bc\}$$

$$^4 B = \{aa, bc, cc\}$$

$$C = \{bb, bb, cc\}$$

	Survived?	No	Yes
⁵ Child		52.00	57.00
Adult		1438.00	654.00

Definition 2.1. For a family of N sets, $F = F_1, F_2, \dots, F_N$, and their $n = 2^N - 1$ intersections, we define ω as the intersections of these sets and their relative complements, such that

$$\begin{aligned}\omega_1 &= F_1 \setminus \bigcap_{j=2}^N F_j \\ \omega_2 &= (F_2 \cap F_3) \setminus \bigcap_{j=3}^n F_j \\ \omega_3 &= \bigcap_{i=1}^3 F_i \setminus \bigcap_{j=4}^N F_j \\ &\vdots \\ \omega_n &= \bigcap_{j=1}^N F_j\end{aligned}$$

with

$$\sum_{i=1}^n \omega_i = \bigcup_{j=1}^N F_j.$$

Analogously to ω , and for convenience, we also introduce the $\&$ operator as

$$F_j \& F_k = (F_j \cap F_k) \setminus (F_j \cap F_k)^C = \omega_i,$$

where i in this instance is the index of the binary identifier of the intersection between F_j and F_k .

With the input translated into a useable form, the Euler diagram is fit in two steps: first, an initial configuration is formed with circles using only the sets' pairwise relationships. Second, this configuration is fine tuned taking all $2^N - 1$ overlaps into account.

2.2 Initial configuration

For our initial configuration we rely on a constrained version of multi-dimensional scaling (MDS) from **venn.js** [10], which is a modification of a method from **venneuler** [5]. In it, we consider the pairwise relationships between the sets and attempt to position their respective shapes so as to minimize the difference between the distance between their centers required to obtain an optimal overlap (ω) and the actual overlap between the shapes in the diagram.

This problem is unfortunately intractable for ellipses, being that there is an infinite number of ways by which we can position two ellipses to obtain a given overlap. Thus, we restrict ourselves to circles, for which we can use the circle-circle overlap formula (2.1) to numerically find the required distance, d , for each set of two ellipses,

$$O_{ij} = r_i^2 \arccos\left(\frac{d_{ij}^2 + r_i^2 - r_j^2}{2d_{ij}r_i}\right) + r_j^2 \arccos\left(\frac{d_{ij}^2 + r_j^2 - r_i^2}{2d_{ij}r_j}\right) - \frac{1}{2}\sqrt{(-d_{ij} + r_i + r_j)(d_{ij} + r_i - r_j)(d_{ij} - r_i + r_j)(d_{ij} + r_i + r_j)}, \quad (2.1)$$

where r_i and r_j are the radii of the circles representing the i :th and j :th sets respectively, O_{ij} their overlap, and d_{ij} the distance between them.

We are looking for d , which we find easily from knowing O and r . Our loss function is the squared difference between O and ω (the desired overlap),

$$\mathcal{L}(d_{ij}) = (O_{ij} - \omega_{ij})^2, \quad \text{for } i < j \leq n \quad (2.2)$$

which we optimize using R's built-in `optimize()`⁶. Convergence is fast and negligible next to our later optimization procedures. For a two-set combination, this is all we need to plot an exact diagram, given that we now have each the two circles' radii, their separation, and can place the circles arbitrarily on a two-dimensional plane as long as d remains the same. This is not, however, with more than two sets, in which case we proceed to the next step.

Given these optimal pairwise distances, we now try to arrange the circles representing the sets for our initial layout. This can be accomplished in many ways; **eulerr**'s approach is based on a method developed by Frederickson [12], which the author describes as constrained multi-dimensional scaling—a form of numeric optimization.

The algorithm tries to position the circles on a plane so that the separation between each pair of circles matches the separation required from (2.2). If the two sets are disjoint, however, it is unconcerned with the relative locations of those circles as long as they do not intersect. The same applies to subset sets: as long as the circle representing the smaller set remains within the larger circle, their locations are free to vary. In all other cases, the loss function (2.3) is the normal sums of squares between the optimal distance between two sets, d , that we found in (2.1) and the actual distance in the layout we are currently exploring.

$$\mathcal{L}(h, k) = \sum_{0 \leq i < j \leq N} \begin{cases} 0 & F_i \cap F_j = \emptyset \text{ and } O_{ij} = 0 \\ 0 & (F_i \subseteq F_j \text{ or } F_i \supseteq F_j) \text{ and } O_{ij} = 0 \\ \left((h_i - h_j)^2 + (k_i - k_j)^2 - d_{ij}^2 \right)^2 & \text{otherwise} \end{cases} \quad (2.3)$$

The analytical gradient (2.4) is retrieved as usual by taking the derivative of the loss function:

Figure 2.1. The circle-circle overlap is computed as a function of the discs' separation (d_{ij}), radii (r_i, r_j), and area of overlap (O_{ij}).

⁶According to the documentation, `optimize()` consists of a "combination of golden section search and successive parabolic interpolation."

$$\vec{\nabla} f(h_i) = \sum_{j=1}^N \begin{cases} \vec{0} & F_i \cap F_j = \emptyset \text{ and } O_{ij} = \emptyset \\ \vec{0} & (F_i \subseteq F_j \text{ or } F_i \supseteq F_j) \text{ and } O_{ij} = \emptyset \\ 4(h_i - h_j) \left((h_i - h_j)^2 + (k_i - k_j)^2 - d_{ij}^2 \right) & \text{otherwise,} \end{cases} \quad (2.4)$$

where $\vec{\nabla} f(k_i)$ is found as in (2.4) with h_i swapped for k_i (and vice versa). Because it speeds up convergence, we also compute the Hessian matrix (2.5). (In our implementation, we only actually use the lower triangle.)

$$H = \sum_{0 \leq i < j \leq N} \begin{bmatrix} 4((h_i - h_j)^2 + (k_i - k_j)^2 - d_{ij}^2) + 8(h_i - h_j)^2 & \cdots & 8(h_i - h_j)(k_i - k_j) \\ \vdots & \ddots & \vdots \\ 8(k_i - k_j)(h_i - h_j) & \cdots & 4((h_i - h_j)^2 + (k_i - k_j)^2 - d_{ij}^2) + 8(k_i - k_j)^2 \end{bmatrix}. \quad (2.5)$$

Note that the constraints given in (2.3) and (2.4) still apply to each element of (2.5) and have been omitted for practical reasons only.

We optimize (2.3) using the nonlinear optimizer `nlmminb()` from the R core package **stats**. The underlying code for `nlmminb()` was written by Gray [13] and was part of the PORT Mathematical Subroutine Library [14]. It was ported to R by Douglas Bates and Deepayan Sarkar [15]. `nlmminb()` consists of a set of complicated routines that seem to perform well for difficult problems [16] and allows bound constraints, which we make use of here by limiting the parameter space so that

$$h_i, k_i \in \left[0, \sqrt{\sum_{i=1}^N r_i^2 \pi} \right].$$

This initial configuration will be perfect for any two-set combination using circles but may need to be adjusted if more circles are used. More pertinently, we have not yet allowed for ellipses in our diagrams.

2.3 Final configuration

We now need to account for all the sets' relationships and, consequently, all the intersections and overlaps in the diagram. Initially, we restricted ourselves to circles but now extend ourselves also to ellipses. From here on we abandon the practice of treating circles separately—they are ellipses and everything that applies to an ellipses does so equally for circles.

As we saw in the [Background](#), we now need to have all the ellipses' points of intersections at hand. **eulerr**'s approach to this is outlined in Richter-Gebert [17] and based in *projective*, as opposed to *euclidean*, geometry.

To collect all the intersection points, we naturally need only to consider two ellipses at a time. The canonical form of an ellipse is given by

$$\frac{[(x-h)\cos\phi + (y-k)\sin\phi]^2}{a^2} + \frac{[(x-h)\sin\phi - (y-k)\cos\phi]^2}{b^2} = 1,$$

where ϕ is the counter-clockwise angle from the positive x-axis to the semi-major axis a , b is the semi-minor axis, and h, k are the x- and y-coordinates, respectively, of ellipse's center. However, because an ellipse is a conic⁷ they can be represented via the quadric form

$$Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0. \quad (2.6)$$

(2.6) can in turn be represented as a matrix,

$$\begin{bmatrix} A & B/2 & D/2 \\ B/2 & C & E/2 \\ D/2 & E/2 & F \end{bmatrix},$$

which is the form we need to intersect our ellipses. We now proceed to

1. form a degenerate conic from the solution to the system consisting of the two conics we wish to intersect,
2. split this degenerate conic into a pencil of two lines, and finally
3. intersect the remaining conic with this pencil, yielding 0 to 4 intersection points (Figure 2.2).

After we have all the intersection points, we find the overlap by examining the intersection points that are formed from the intersections of the ellipses we are currently exploring and that are simultaneously contained within all of these ellipses. The elliptical arcs that connect these points along with the polygon with sides formed from joining the points with straight lines together make up the area of the overlap (?? 8).

Since the polygon part is always convex, it is easy to find its area using the *triangle method*. To find the areas of the elliptical segments, we first order all the points in clockwise order⁸. Then, we acknowledge that each elliptical segment is formed from an arc of the ellipse that is shared by both points⁹. Now that we have two points on an ellipse, we can find the area of the ellipse segment using an algorithm from Eberly [18]. To proceed, we

1. center their ellipse at $(0, 0)$,
2. normalize its rotation, which is not needed to compute the area,
3. integrate the ellipse from 0 to ϕ_0 and ϕ_1 to produce two elliptical sectors,
4. subtract the smaller of these sectors from the larger, and

⁷The circle, parabola, and hyperbola are also conics.

Figure 2.2. The process (from top to bottom) used to intersect two ellipses, here yielding four points.

⁸It makes no difference if we sort them in counter-clockwise order instead.

⁹Because there is sometimes two arcs connecting the pairs of points, we simply compute both areas and pick the smaller.

Figure 2.3. The overlap area between three ellipses is the sum of a convex polygon (in grey) and 2-3 ellipse segments (in blue).

5. subtract the triangle section to finally find the segment area (10).

$$\alpha(\theta_0, \theta_1) = F(\theta_1) - F(\theta_0) - \frac{1}{2} |x_1 y_0 - x_0 y_1|,$$

$$\text{where } F(\theta) = \frac{a}{b} \left[\theta - \arctan \left(\frac{(b-a) \sin 2\theta}{b+a+(b-a) \cos 2\theta} \right) \right]$$

This procedure is illustrated in Figure 2.4.

The exact algorithm may in rare instances¹⁰, break down. The culprit is numerical approximation issues that occur because ellipses are close-to tangent to one another or completely overlap. In these cases, the algorithm will resort to approximation of the involved overlap area by

1. spreading points across the ellipses using Vogel's method (see Labeling for a brief introduction),
2. identifying the points that are inside the intersection via the inequality

$$\frac{[(x-h) \cos \phi + (y-k) \sin \phi]^2}{a^2} + \frac{[(x-h) \sin \phi - (y-k) \cos \phi]^2}{b^2} < 1,$$

where x and y are the coordinates of the sampled points, and finally

3. approximating the area by multiplying the proportion of points inside the overlap with the area of the ellipse.

With this in place, we are now able to compute the areas of all intersections and their relative complements up to numerical precision. We feed the initial layout computed in Initial configuration to the

Figure 2.4. The elliptical segment in blue is found by first subtracting the elliptical sector from $(a, 0)$ to θ_0 from the one from $(a, 0)$ to θ_1 and then subtracting the triangle part (in grey).

¹⁰1 out of approximately 7000 in our simulations.

optimizer—once again we employ `nlminb()` from **stats** but now also provide the option to use ellipses rather than circles, allowing the "circles" to rotate and the relation between the semiaxes to vary, altogether rendering five parameters to optimize per set and ellipse (or three if we restrict ourselves to circles). For each iteration of the optimizer, the areas of all intersections are analyzed and a measure of loss returned. The loss we use is the sum of squared errors between the ideal sizes (ω from Definition 2.1) and the respective areas of the diagram,

$$\sum_{i=1}^n (A_i - \omega_i)^2 \quad (2.7)$$

2.4 Goodness of fit

If we are using ellipses and are faced with a substantial error, we offer a final step in which we pass the parameters on to a *Generalized Simulated Annealing* optimizer from the R package **GenSA** [19]. `GenSA()` is a suitable optimizer for complicated functions with many local minima [20], which is precisely what a Euler diagram with ellipses is.

By default, this step is activated only when we have a three-set diagram with ellipses and our `diagError` (2.9) surpasses 0.001¹¹. The reason being that the method is considerably more intensive computationally.

When **eulerr** cannot find a perfect solution it offers an approximate one instead, the adequacy of which has to be measured in a standardized way. For this purpose we adopt two measures: *stress* [5] and *diagError* [3].

The stress metric is the residual sums of squares over the total sums of squares,

$$\text{Stress} = \frac{\sum_{i=1}^n (\omega_i - A_i)^2}{\sum_{i=1}^n (A_i - \bar{A})^2}, \quad (2.8)$$

where \bar{A} is the arithmetic mean of the areas in the diagram.

The stress metric does not lend itself readily to a clear-cut interpretation but can be transformed into a rough analogue of the correlation coefficient by $r = \sqrt{1 - \text{stress}^2}$.

`diagError`, meanwhile, is given by

$$\text{diagError} = \max_{i=1,2,\dots,n} \left| \frac{\omega_i}{\sum_{i=1}^n \omega_i} - \frac{A_i}{\sum_{i=1}^n A_i} \right|, \quad (2.9)$$

which is the maximum absolute difference of the proportion of any ω to the respective unique area of the diagram.

¹¹ The user, however, is free to choose if and when to activate the optimizer using standard arguments to the main function of the package.

3 Results

The only R packages that feature area-proportional Euler diagrams are **eulerr**, **venneuler**, **Vennerable**, and **d3VennR**. The latter is an interface to the **venn.js** script that has been discussed previously, but because it features an outdated version of the script and only produces images as html, we call **venn.js** directly using the javascript engine **V8** via the R package of the same name. Only **eulerr**, **venn.js**, and **venneuler** support more than three sets, which is why there are only three-set results for **Vennerable** and **eulerAPE**.

The packages used here were

- **eulerr** 3.0.0,
- **eulerAPE** 3.0.0,
- **venn.js** 0.2.14,
- **venneuler** 1.1-0, and
- **Vennerable** 3.1.0.9000.

The results for **eulerAPE** were computed on a laptop computer¹²
The remaining results were computed on an Amazon EC2 cloud-based computing instance¹³

3.1 Case studies

We begin our examination of **eulerr** by studying a difficult set relationship from Wilkinson [5],

$$\begin{aligned} A &= 4 & B &= 6 & C &= 3 & D &= 2 & E &= 7 & F &= 3 \\ A \& B &= 2 & A \& F &= 2 & B \& C &= 2 & B \& D &= 1 \\ B \& F &= 2 & C \& D &= 1 & D \& E &= 1 & E \& F &= 1 \\ A \& B \& F &= 1 & B \& C \& D &= 1, \end{aligned}$$

where we use the $\&$ operator as defined in [Definition 2.1](#). We fit this specification with **venneuler** and **eulerr**, in the latter case using both circles and ellipses ([Figure 3.1](#)).

This example showcases the improvement gained from using ellipses and also the small benefit that **eulerr** offers relative to **venneuler**.

¹²The specification of the computer was

- Microsoft Windows Pro 10 x64
- Intel® Core™ i7-4500U CPU @ 1.80GHz, 2 cores
- 8 GB memory

¹³ This was a m4.large instance with the following specifications:

- Ubuntu 16.04 x64
- 2.4 GHz Intel Xeon®E5-2676 v3 (Broadwell) CPU, 2 cores
- 8 GB memory

Figure 3.1. A comparison of a Euler diagram generated with **venneuler** with two generated from **eulerr** with circles and ellipses respectively. The stress of the solutions are 0.006, 0.004, and 0.000 respectively.

Micallef and Rodgers [3] featured a diagram from Lenz and Fornoni [21]. We will not dwell upon the inaccuracies of the original diagram here but rather contrast the results of **eulerAPE** with those of **eulerr**. The data from the original diagram was

$$\begin{aligned} A &= 0.36, & B &= 0.03, & C &= 0, \\ A \& B &= 0.41, & A \& C &= 0.04, & B \& C &= 0, & \text{ and} \\ A \& B \& C &= 0.11. \end{aligned}$$

However, because **eulerAPE** cannot fit diagrams that lack some intersections, instead replaced 0 with 0.00001. Since the diagram was reproduced with ellipses, we will do the same with **eulerr** but set the areas as they are in the original data.

The fits from both packages are exact (Figure 3.2). Although we told **eulerr** to use ellipses in the fit, the algorithm stuck to circles, which, given that the fit is exact, is the appropriate choice since circles are easier to interpret. The reason **eulerAPE** did not is that it tries to keep the three shapes intersecting (albeit marginally), which cannot be done with circles if the layout is to be exact.

We also note that the labels of the nonexistent overlaps in the diagram from **eulerAPE** have been placed at seemingly arbitrary locations. In the original publication [3], the labels were manually adjusted.

Figure 3.2. Diagrams from **eulerAPE** and **eulerr** based on data from a diagram in Lenz and Fornoni [21]. The diagrams have not been modified in any way save for converting the diagram from **eulerAPE** from .svg to .pdf.

	Amelie	Pulp Fiction	Miss Congeniality	Armageddon	Rashomon	Coyote Ugly
Amelie	38,753					
Pulp Fiction	15,197	70,153				
Miss Congeniality	1,829	3,854	37,837			
Armageddon	1,218	6,593	10,536	40,345		
Rashomon	2,087	2,799	132	143	6,209	
Coyote Ugly	610	2,206	5,965	5,699	38	15,611

Table 3.1. The data from the Netflix Prize dataset used in Fredrickson [22].

To conclude the case studies part of this thesis, we look at a diagram that was featured on website of the author of **venn.js** [22], which used the *Netflix Prize Dataset*¹⁴ from which he

[...] picked 6 movies, kind of at random – and then represented them using the set of users that gave the movie a 5 star rating.

¹⁴The dataset is no longer available on this webpage, but can be found at <https://www.kaggle.com/netflix-inc/netflix-prize-data> for those who are interested.

The movies were Amelie, Pulp Fiction, Miss Congeniality, Armageddon, Rashomon, and Coyote Ugly. The data only includes pairwise relationships (Table 3.1).

It is not obvious which of the two fits are better. The stress and diagError from the **eulerr** diagram (Figure 3.4a) is 0.029 and 0.058 respectively, whilst the same figures are 0.004 and 0.262 for the **venn.js** diagram (Figure 3.4b).

(a) The fit from **eulerr** with a stress of 0.029 and diagError of 0.058.

(b) The fit from **venn.js** with a stress of 0.004 and diagError of 0.262.

Figure 3.4. The Euler diagrams generated from the Netflix Prize data. Notice the different choices made by the algorithms.

Another option is of course to try to fit the diagram with ellipses instead (Figure 3.5). We are now able to reduce our diagError to 0.014 and our stress to 0.003, which is mostly the result of being able to

dispose of all the three-way intersections that were implicitly set to 0 when we fit our diagram.

Figure 3.5. The data from Table 3.1 visualized with ellipses.

3.2 Consistency

To compare the consistency among **eulerr**, **venneuler**, **eulerAPE**, **venn.js**, and **Vennerable**, we generate random diagrams of circles and ellipses, compute their areas, and attempt to reproduce the original diagram using the software packages that we are studying. We restrict ourselves to diagrams consisting of between 3 and 8 shapes.

For the circles, we sample radii (r_i) and coordinates (h_i and k_i) from

$$\begin{aligned} r_i &\sim \mathcal{U}(0.2, 0.6) \\ h_i, k_i &\sim \mathcal{U}(0, 1), \end{aligned} \tag{3.1}$$

where N is the number of shapes. For the ellipses, we sample semi-axes (a_i and b_i), coordinates (h_i and k_i), and rotation axes (ϕ_i) from

$$\begin{aligned} h_i, k_i &\sim \mathcal{U}(0, 1) \\ r_i &\sim \mathcal{U}(0.2, 0.6) \\ c_i &\sim \mathcal{U}(1/2, 2) \\ a_i &= r_i c_i \\ b_i &= r_i / c_i \\ \phi_i &\sim \mathcal{U}(0, \pi), \end{aligned} \tag{3.2}$$

where c is the ratio between the semiaxes.

Next, we compute the required areas, ω (from Definition 2.1), for each iteration and fit a Euler diagram using the aforementioned packages. Finally, we compute and return *diagError* (2.9) and score each diagram as a *success* if its *diagError* is lower than 0.01, that

```

for  $i \leftarrow 3$  to 8 do
  while length of each  $I(p_s)_{0.95} < 2\%$  and  $j < 500$  do
    if circle then
       $h, k \leftarrow \mathcal{U}(0, 1)$ 
       $r \leftarrow \mathcal{U}(0.3, 0.6)$ 
       $\omega \leftarrow \text{findOverlaps}(h, k, r)$ 
    else if ellipse then
       $h, k \leftarrow \mathcal{U}(0, 1)$ 
       $a, b \leftarrow \mathcal{U}(0.2, 0.8)$ 
       $\phi \leftarrow \mathcal{U}(0, 2\pi)$ 
       $\omega \leftarrow \text{findOverlaps}(h, k, a, b, \phi)$ 
     $A \leftarrow \text{fitDiagram}(\omega)$ 
     $\text{diagError}_j \leftarrow \max_{k=1,2,\dots,2^i-1} \left| \frac{\omega_k}{\sum \omega_k} - \frac{A_k}{\sum A_k} \right|$ 
    if  $\text{diagError}_j < 0.01$  then  $\text{successes} + 1$ 
    foreach  $s \leftarrow \text{software package}$  do
       $\hat{p}_s \leftarrow \text{successes}/j$ 
       $I(\hat{p}_s)_{0.95} \leftarrow \hat{p} \pm z_{0.95} \sqrt{\frac{\hat{p}_s(\hat{p}_s-1)}{n}}$ 

```

Algorithm 3.1. The algorithm used to simulate circles and ellipses, compute their areas, and fit Euler diagrams to these layouts using the different software packages.

is, if no portion of the diagram is 1% off (in absolute terms) from that of the input; note that this is always achievable since our Euler diagrams are formed from sampled diagrams.

For each number of shapes ($i = 3, 4, \dots, 8$) we run the simulations until we have achieved a 95% confidence interval around \hat{p} , the proportion of successful diagrams, that is no wider than 2%. The confidence that we generate is the standard asymptotic interval,

$$I(\hat{p})_{0.95} = \hat{p} \pm z_{0.95} \sqrt{\frac{\hat{p}(\hat{p}-1)}{n}}$$

The algorithm is formalized in [Algorithm 3.1](#). The left panel of [Figure 3.6](#) shows the results of our simulation.

eulerr outperforms both **Vennerable** and **venneuler** in consistency ([Figure 3.6](#)). It is able to reproduce Euler diagrams for almost all of the circles and for all three-set ellipses. For ellipses of four or more sets, the consistency drops considerably, yet remains above 69.207%. **Vennerable**, which is only able to produce three-set diagrams, only produces accurate diagrams for 5.526% of the random layouts and moreover fails with an error in 211 cases.

3.3 Accuracy

In [Consistency](#), we assess the efficacy in reproducing diagrams with exact, but unknown, solutions. In real situations, however, we are often faced with set configurations that lack exact solutions, in which case we want our method to produce an approximation that is as accurate as possible.

3 Results

Figure 3.6. Reproducibility tests for ellipses and circles generated from the distributions from (3.1). Note that **Venerable** and **eulerAPE** only support Euler diagrams for three sets, which is why its data is absent for the other cases.

```

for  $i \leftarrow 3$  to 8 do
  while length of each  $\mathcal{I}(\hat{\mu}_s)_{0.95} < 0.02$  and  $j < 500$  do
    initialize  $\omega = \{\omega_1, \omega_2, \dots, \omega_{2^i-1}\}$  to zero
    for  $j \leftarrow 3$  to  $i$  do
       $j \leftarrow$  random index in  $\{\omega : \omega \cap F_i \neq \emptyset\}$ 
       $\omega_j \leftarrow \mathcal{U}(0, 1)$ 
     $\omega_S \leftarrow \mathcal{U}\{0, i\}$  random elements from  $\{\omega : \omega = 0\}$ 
     $\omega_S \leftarrow \mathcal{U}(0, 1)$ 
    fit a Euler diagram to  $\omega$ 

```

Algorithm 3.2. The algorithm we use to simulate random set relationships and fit them with the software under study to assess their accuracy.

To assess this, we generate random set relationships, that may or may not have exact solutions, and fit Euler diagram using the software under study. For each $i = 3, 4, \dots, 8$ sets we initialize $2^i - 1$ permutations of set combinations, select one for each set, and initialize these to a number in $\mathcal{U}(0, 1)$. After this, we pick 0 to $\binom{N-2}{1}$ elements from the $2^i - i - 1$ remaining permutations and assign to them a number from $\mathcal{U}(0, 1)$ as before.

As in [Consistency](#), we run our simulations until we have achieved a desired confidence interval for the estimates. This time, we keep on going until we have a 95% confidence interval no longer than 0.02 in mean diagError. We use the common confidence level based on the t-distribution,

$$\mathcal{I}(\hat{\mu})_{0.95} = \hat{\mu} \pm t_{0.95} \frac{s}{\sqrt{n}}, \quad (3.3)$$

where $\hat{\mu} = \bar{x}$. The algorithm is formalized in [Algorithm 3.2](#)

The error in the diagrams generated with **eulerr** is considerably lower than for the other methods. This is most apparent with ellipses but also true for circles compared to **venneuler** and **Venerable**.

3 Results

Figure 3.7. Accuracy tests of set relationships that may or may not have perfect solutions, generated from (3.2).

3.4 Performance

Using the same method as in [Accuracy](#), we generate random set relationships and measure the time it takes for each software package to form a diagram from the fit. We rely on **microbenchmark** to compute this, subtracting function call times to produce strict measurement. In addition, we randomize the order in which the packages are called between trials.

Figure 3.8. Performance of **eulerr**, **venneuler**, and **Vennerable** on random set relationships of 3 to 8 sets

3.5 Availability

eulerr is available as an R package on the CRAN network [23] and is installed simply by typing

```
install.packages("eulerr")
```

A development version and the source code for the project is maintained in a GitHub repository at <https://github.com/jolars/eulerr>. This version can be installed, provided that the **devtools** package is installed, with the following oneliner:

```
devtools::install_github("jolars/eulerr")
```

The source code for this thesis, meanwhile, is also provided in a GitHub repository at <https://github.com/jolars/eulerrPaper>, which also hosts the code used to generate the results for this thesis is provided.

Finally, there is a **shiny** [24] web application for **eulerr** at <http://jolars.co/eulerr>, which features a slightly slimmed-down version of the package that is available to everyone with a internet connection and somewhat-recent web browser.

4 Discussion

In this paper, we have presented a novel method for generating Euler diagrams for any number of sets using ellipses. We have shown that the method is superior in both accuracy and consistency next to all other software packages for R—even when the method is restricted to circles. In addition, the method is speedier than the competition for set relationships with up to six sets, wherafter it performs worse than **venneuler**.

In terms of consistency and accuracy, there are several reasons for why **eulerr** improves upon the method in **venneuler** and **Ven-nerable**. The primary reason lies in the use of ellipses rather than circles. Ellipses feature two additional degrees of freedom and are therefore able to accurately represent a larger variety of relationships.

Moreover, the initial optimizer in **eulerr** circumvents a rule in **venneuler** that puts unnecessary restrictions on layouts that include disjoint or subset relationships. The initial optimizer in **venneuler** places disjoint and subset circles exactly neck-in-neck and at the exact midpoint of the set respectively. Yet, because we are indifferent about where in the space outside (or respectively inside) the circles are placed, that behavior becomes problematic since it might interfere with locations of other sets that need to use that space. The MDS algorithm from **venn.js** circumvents this by assigning a loss and gradient of zero when the pairwise set intersection *and* the candidate circles are disjoint or subset.

For 3 to 7 sets, **eulerr** is speedier than both **Ven-nerable** and **venneuler**. The reasons for this is partly to do with the implementation in C++ using high-performance interfaces such as **Rcpp** [25] and **RcppArmadillo** [26]. For few sets, the exact-area calculations that **eulerr** features also promote better performance; yet, paradoxically, this also happens to be the reason for why the performance of **eulerr** suffers as the number of sets surge. The bottleneck is the final optimizer. It has to examine every possible intersection when computing the areas, thus converging in $O(2^n)$ time. Wilkinson [5], meanwhile, report convergence in $O(n)$ time. This is clearly evidenced in Figure 3.8. Future versions of this algorithm might consider implementing approximate area-calculations when the number of sets is large.

This method was first published for circles in a blog post [11] and in a scholarly paper for up to three ellipses [3] but has to our knowledge not previously been generalized to any number of ellipses.

4 *Discussion*

The authors motivate this limitation by the propensity of Euler diagrams with more sets to lack adequate solutions and that their complexity make implementations difficult [9].

Appendices

A Visualization

Once we have ascertained that our Euler diagram fits well, we can turn to visualizing the solution. For this purpose, **eulerr** leverages the **Lattice** graphics system [27] for R to offer intuitive and granular control over the output.

Plotting the ellipses is straightforward using the parametrization of a rotated ellipse,

$$\begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} h + a \cos \theta \\ k + b \sin \theta \end{bmatrix}, \quad \text{where } \theta \in [0, 2\pi].$$

Often, however, we would also like to label the ellipses and their intersections with text and this is considerably more involved.

A.1 Labeling

Labeling the ellipses is difficult because the shapes of the intersections often are irregular, lacking a well-defined center; we know of no analytical solution to this problem. As usual, however, the next-best option turns out to be a numerical one. First, we locate a point that is inside the required region by spreading points across the discs involved in the set intersection. To distribute the points, we use a modification of *Vogel's method* [28, 29] adapted to ellipses. Vogel's method spreads points across a disc using

$$p_k = \begin{bmatrix} \rho_k \\ \theta_k \end{bmatrix} = \begin{bmatrix} r \sqrt{\frac{k}{n}} \\ \pi(3 - \sqrt{5})(k - 1) \end{bmatrix} \quad \text{for } k = 1, 2, \dots, n. \quad (\text{A.1})$$

In our modification, we scale, rotate, and translate the points formed in (A.1) to match the candidate ellipse. We rely, as before, on projective geometry to carry out the transformations in one go:

$$p' = \begin{bmatrix} x' \\ y' \\ 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & h \\ 0 & 1 & k \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos \phi & \sin \phi & 0 \\ -\sin \phi & \cos \phi & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} a & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \hat{x} \\ \hat{y} \\ 1 \end{bmatrix}$$

After we spread our points throughout the ellipse and find a point, p'_i , that is contained in our desired intersection, we proceed to optimize its position numerically. The position we are looking for is that which maximizes the distance to the closest ellipse in our diagram to provide as much margin as possible for the label. This is a maximin problem with a loss function equal to

$$\max_{x, y \in \mathbb{R}^2} \min_{i=1, 2, \dots, N} f(x, y, h_i, k_i, a_i, b_i, \phi_i) \quad (\text{A.2})$$

where f is the function that determines the distance from a point (x, y) to the ellipse defined by h, k, a, b and ϕ .

Similarly to fitting Euler diagrams in the general case, there appears to be no analytical solution to computing the distance from a point to an ellipse. The numerical solution we use has been described in Eberly [30] and involves solving the roots to a quartic polynomial via a robust bisection optimizer.

To optimize the location of the label, we employ a version of the *Nelder–Mead Method* [31] which has been translated from Kelley [32] and adapted for **eulerr** to ensure that it covers quickly and that the simplex remains within the intersection boundaries (since we want the local maximum). The method is visualized in Figure A.1.

A.2 Aesthetics

Euler diagrams display both quantitative and qualitative data. The quantitative aspect is the quantities or sizes of the sets depicted in the diagram and is visualized by the relative sizes, and possibly the labels, of the areas of the shapes—this is the main focus of this paper. The qualitative aspects, meanwhile, consist of the mapping of each set to some quality or category, such as having a certain gene or not. In the diagram, these qualities can be separated through any of the following aesthetics:

- color,
- border type,
- text labelling,
- transparency,
- patterns,

or a combination of these. The main purpose of these aesthetics is to separate out the different ellipses so that the audience may interpret the diagram with ease and clarity.

Among these aesthetics, the best choice (from a viewer perspective) appears to be color [7], which provides useful information without extraneous chart junk [33]. The issue with color, however, is that it cannot be perceived perfectly by all—8% of men and 0.4% of women in European Caucasian countries, for instance, suffer the most common form, red–green color deficiency [34]. Moreover, color is often printed at a premium in scientific publications and adds no information to a diagram of two shapes.

For these reasons, **eulerr** defaults to distinguishing ellipses with color using a color palette generated via the R package **qualpalr** [35], which automatically generates qualitative color palettes based on a perceptual model of color vision that optionally caters to color

Figure A.1. The method **eulerr** uses to locate an optimal position for a label in three steps from top to bottom: first, we spread sample points on one of the ellipses and pick one inside the intersection of interest, then we begin moving it numerically, and finally place our label.

vision deficiency. This palette has been manually modified to fulfill our other objectives of avoiding using colors for two sets. The first eight colors of the palette are visualized in Figure A.2.

Figure A.2. The eight first colors of the default color palette.

A.3 Normalizing dispersed layouts

If there are disjoint clusters of ellipses, the optimizer will often spread these out more than is necessary, wasting space in our diagram. To tackle this, we use a SKYLINE-BL rectangle packing algorithm [36] designed specifically for **eulerr**. In it, we surround each ellipse cluster with a bounding box, pack these boxes into a bin of appropriate size and aspect ratio, and adjust the coordinates of the ellipses in the clusters to compact our diagram.

As a bonus, this also increases the chance of having similar layouts for different function calls even when we do not fix the random seed.

B Usage

`euler()` and `plot()` are the only functions that a user of **eulerr** need concern themselves with. In [Input](#), we described the various forms of input that the function can be supplied with. Using the first form, we will showcase how a Euler diagram is fit. For this example, we use a diagram from a publication by Junta et al. [37] that was also showcased in Wilkinson [5]. We load the package, specify our diagram, and fit it using `euler()` as follows.

```
library(eulerr)
junta_2009 <- c("SE" = 13, "Treat" = 28, "Anti-CCP" = 101,
               "DAS28" = 91, "SE&Treat" = 1, "SE&DAS28" = 14,
               "Treat&Anti-CCP" = 6, "SE&Anti-CCP&DAS28" = 1)
fit1 <- euler(junta_2009)
```

Printing the results provides a summary of the fit, including the *stress* and *diagError* metrics that were introduced in [Goodness of fit](#).

```
fit1 # or equivalently print(fit1)
```

##	original	fitted	residuals	regionError
## SE	13	13	0	0.000
## Treat	28	28	0	0.000
## Anti-CCP	101	101	0	0.002
## DAS28	91	91	0	0.001
## SE&Treat	1	1	0	0.000
## SE&Anti-CCP	0	0	0	0.000
## SE&DAS28	14	14	0	0.000
## Treat&Anti-CCP	6	6	0	0.000
## Treat&DAS28	0	0	0	0.000
## Anti-CCP&DAS28	0	0	0	0.000
## SE&Treat&Anti-CCP	0	0	0	0.000
## SE&Treat&DAS28	0	0	0	0.000
## SE&Anti-CCP&DAS28	1	0	1	0.004
## Treat&Anti-CCP&DAS28	0	0	0	0.000
## SE&Treat&Anti-CCP&DAS28	0	0	0	0.000
##				
## diagError:	0.004			
## stress:	0			

The fit is more or less equivalent to that of **venneuler** [5]. There is an error but it is small at a `diagError` of 0.004. We could, however, try to improve the fit using ellipses:

B Usage

```
# Fit the data using ellipses instead
fit2 <- euler(junta_2009, shape = "ellipse")

# Compare the fits on diagError
fit1$diagError - fit2$diagError

## [1] 0
```

Comparing the two fits in `diagError`, however, shows that we have not bettered the fit in any meaningful way. Our next goal is to visualize the layout, which we do both using the default options and by customizing the fit, adding counts, replacing the sets' labels with a key, removing lines, and changing the fills using the **RColorBrewer** package (Figure B.1).

```
p1 <- plot(fit1)
p2 <- plot(fit1,
  counts = list(fontface = 3),
  fill = RColorBrewer::brewer.pal(4, "Set2"),
  border = "transparent",
  auto.key = list(space = "right")) # key on the right
```

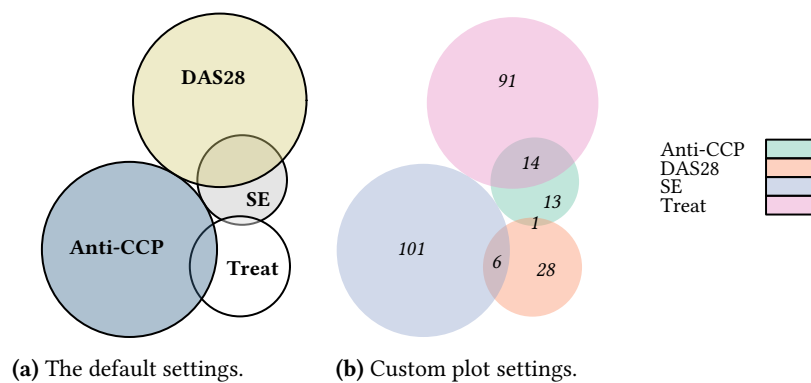

Figure B.1. The same fit visualized in two distinct ways.
